Multi-Frequency Co-Prime Arrays for High-Resolution Direction-of-Arrival Estimation

Elie BouDaher, Student Member, IEEE, Yong Jia, Fauzia Ahmad, Senior Member, IEEE, and Moeness G. Amin, Fellow, IEEE

Abstract - This paper presents multi-frequency operation for increasing the number of resolvable sources in high-resolution direction-of-arrival (DOA) estimation using co-prime arrays. A single-frequency operation requires complicated and involved matrix completion to utilize the full extent of the degrees of freedom (DOFs) offered by the co-prime configuration. This processing complexity is attributed to the missing elements in the corresponding difference coarray. Alternate single-frequency schemes avoid such complexity by utilizing only the filled part of the coarray and, thus, cannot exploit all of the DOFs for DOA estimation. We utilize multiple frequencies to fill the missing coarray elements, thereby enabling the co-prime array to effectively utilize all of the offered DOFs. The sources are assumed to have a sufficient bandwidth to cover all the required operational frequencies. We consider both cases of sources with proportional and nonproportional power spectra at the employed frequencies. The former permits the use of multi-frequency measurements at the co-prime array to construct a virtual covariance matrix corresponding to a filled uniformly spaced coarray at a single frequency. This virtual covariance matrix can be employed for DOA estimation. The nonproportionality of the source spectra casts a more challenging situation, as it is not amenable to producing the same effect as that of an equivalent single-frequency filled coarray. Performance evaluation of the multi-frequency approach based on computer simulations is provided under both cases of proportional and nonproportional source spectra.

Index Terms — Co-prime arrays, DOA estimation, coarray, multiple frequencies, augmented matrices.

I. INTRODUCTION

Nonuniform linear arrays provide the ability to estimate the direction-of-arrival (DOA) of more sources than the number of physical sensors [1]-[6]. Recently, a new structure of nonuniform linear arrays, known as co-prime arrays, has been proposed [7], [8]. A co-prime configuration comprises two undersampled uniformly spaced subarrays with co-prime spatial sampling rates. Co-prime configurations have many advantages over other popular nonuniform configurations, including minimum redundancy arrays (MRA) [9], minimum hole arrays (MHA) [10], and nested arrays [11]. For a given number of physical sensors, MRAs and MHAs require an exhaustive search through all possible combinations of the sensors to find the optimal design [12], [13]. On the other hand, the positions of the sensors constituting the co-prime configuration have closed-form expressions. Although the same is true of nested arrays, the elements of one of the subarrays constituting the nested structure are closely separated, which may lead to problems due to mutual coupling between the sensors. Co-prime arrays reduce the mutual coupling between most adjacent sensors by spacing them farther apart [7]. Because of all of the aforementioned characteristics, co-prime arrays are finding broad applications in the areas of communications, radar, and sonar [14]-[20].

Similar to other nonuniform arrays, high-resolution DOA estimation with co-prime arrays can be performed using two main approaches. The first approach employs covariance matrix augmentation [21]-[23], while the second method vectorizes the data covariance matrix to emulate observations at a virtual array whose elements are given by the difference coarray (the set of all spatial lags generated by the physical array [24]) [8], [11]. Since the difference coarray of a co-prime array contains multiple missing elements or ‘holes’, the latter approach employs only that part of the difference coarray which has contiguous elements with no holes. As such, only a subset of the total degrees of freedom (DOFs) offered by the co-prime structure can be utilized for high-resolution DOA estimation using the vectorized covariance matrix approach. The augmented
covariance matrix approach, on the other hand, can exploit all the DOFs but at the expense of additional complicated matrix completion processing [23].

In this paper, we consider multi-frequency operation to utilize all of the DOFs for DOA estimation in co-prime arrays. More specifically, a set of additional frequencies is employed to recover the missing lags through dilations of the coarray [25]. The sources are assumed to have a bandwidth large enough to cover all specific frequencies required for filling the holes. Only the array elements involved in filling the missing holes in the difference coarray are required to be operated at one or more of the additional frequencies. The multi-frequency measurements are used to construct a virtual covariance matrix corresponding to an equivalent filled uniformly spaced coarray at a single frequency [26]. High-resolution subspace techniques, such as MUSIC [27], can then be applied to this virtual covariance matrix for DOA estimation. It is important to note that full utilization of the DOFs using multiple additional frequencies comes with a restriction on the sources’ spectra. More specifically, the source spectra at all operational frequencies are required to be proportional. Deviations from this restriction can lead to higher DOA estimation errors.

Multiple frequencies have previously been used for alias-free DOA estimation of broadband sources [28], [29]. In [28], frequency diversity was exploited on a single spatial sampling interval to mitigate spatial aliasing in DOA estimation with a sparse nonuniformly spaced array. Ambiguities in the source location estimates were resolved by proper choice of chosen operational frequencies in [29] for arrays with periodic spatial spectra. Spatial sampling interval diversity at a single narrowband frequency was exploited in [7] to disambiguate aliased DOAs. Both spatial sampling and frequency diversity were exploited in [26] through multi-frequency coarray augmentation for high-resolution DOA estimation. However, no attempt was made therein to select the best number of employed frequencies or determine their best values. We effectively apply the multi-frequency coarray augmentation to co-prime arrays in this paper. Our main contribution lies in exploiting the specific structure of the coarray corresponding to co-prime configuration to determine the number and values of the additional frequencies required for recovering the missing lags. We provide closed-form expressions for the additional frequencies, which are ‘best’ in the sense of minimum operational bandwidth requirements. We also describe when and how the redundancy in the coarray can be exploited to reduce the system hardware complexity for multi-frequency co-prime arrays. Further, we investigate the effects of noise and deviation from the proportional source spectra constraint on the DOA estimation performance of the multi-frequency co-prime arrays.

The remainder of the paper is organized as follows. The single-frequency based high-resolution DOA estimation using co-prime arrays is reviewed in Section II. In Section III, we describe the multi-frequency approach for filling the missing elements in the coarray and utilizing all the DOFs offered by the co-prime configuration for DOA estimation. Section IV delineates the system bandwidth requirement for the multi-frequency operation, taking into account the specificities of the coarray structure corresponding to co-prime arrays. Coarray redundancy is also examined to reduce the number of antennas engaging in multiple frequency operation. In Section V, performance of the proposed method is evaluated through extensive simulations under both proportional and nonproportional source spectra and Section VI concludes the paper.

II. HIGH-RESOLUTION DOA ESTIMATION USING SINGLE-FREQUENCY CO-PRIME ARRAYS

A co-prime array consists of two undersampled uniform linear subarrays, one having \( M \) sensors positioned at \( \{ N m d_0, 0 \leq m \leq M - 1 \} \), and the other comprising \( N \) sensors with positions \( \{ N m d_0, 0 \leq n \leq N - 1 \} \) [11], \( M \) and \( N \) being co-prime integers and \( d_0 \) equal to one-half wavelength at the operating frequency \( \omega_0 \). Without loss of generality, we assume \( M < N \). With the two subarrays sharing the element at location 0, the co-prime array has a total of \( M + N - 1 \) physical sensors. The element positions of the corresponding difference coarray form the set

\[
S_0 = \{ \pm (M N d_0 - N m d_0) \}, \quad 0 \leq n \leq N - 1, \\
0 \leq m \leq M - 1,
\]

which extends from \( -N(M - 1)d_0 \) to \( N(M - 1)d_0 \), but only the elements from \( -(M + N - 1)d_0 \) and \( (M + N - 1)d_0 \) are contiguous. As such, high-resolution schemes, such as MUSIC, can estimate only up to \( M + N - 1 \) sources.

An extended co-prime configuration was proposed in [8], wherein the number of elements in the subarray with fewer sensors were doubled, as depicted in Fig. 1. The difference coarray of this configuration, shown in Fig. 2, extends from \( -(2M - 1)N d_0 \) to \( (2M - 1)N d_0 \), and has a contiguous set of elements between \( -(MN + M - 1)d_0 \) and \( (MN + M - 1)d_0 \). Thus, high-resolution DOA estimation can be performed to estimate \( (MN + M - 1) \) sources using the extended co-prime configuration. We will consider the extended co-prime configuration with \( M < N \) in the remainder of this paper.

Assume that \( D \) sources with powers \( \sigma_1^2(\omega_0), \sigma_2^2(\omega_0), \ldots, \sigma_D^2(\omega_0) \) impinge on the extended
co-prime array from directions $[\theta_1, \theta_2, \ldots, \theta_D]$ where $\theta$ is measured relative to broadside. The received data vector at frequency $\omega_0$ can be expressed as

$$\mathbf{x}(\omega_0) = \mathbf{A}(\omega_0)\mathbf{s}(\omega_0) + \mathbf{n}(\omega_0),$$

(2)

where $\mathbf{s}(\omega_0) = [s_1(\omega_0) \ s_2(\omega_0) \ldots s_D(\omega_0)]^T$ is the source signal vector at $\omega_0$, $\mathbf{n}(\omega_0)$ is the corresponding noise vector, $\mathbf{A}(\omega_0)$ is the array manifold matrix at $\omega_0$, and the superscript $(\cdot)^T$ denotes matrix transpose. The $(i,j)$th element of the array manifold can be expressed as

$$[\mathbf{A}(\omega_0)]_{ij} = e^{j k_0 x_i \cos(\theta_j)}, \quad i = 1, \ldots, 2M + N - 1, \quad j = 1, 2, \ldots, D,$$

(3)

where $x_i$ is the location of the $i$th physical sensor of the array, $\theta_j$ is the DOA of the $j$th source, and $k_0 = \omega_0/c$ is the wavenumber at $\omega_0$ with $c$ being the speed of propagation in free space. Assuming that the sources are uncorrelated and the noise is spatially and temporally white, the covariance matrix is obtained as

$$\mathbf{R}_{xx}(\omega_0) = E\{\mathbf{x}(\omega_0)\mathbf{x}^H(\omega_0)\}$$

$$= \mathbf{A}(\omega_0)\mathbf{R}_{ss}(\omega_0)\mathbf{A}^H(\omega_0) + \sigma_n^2(\omega_0)\mathbf{I},$$

(4)

where $\mathbf{R}_{ss}(\omega_0) = \text{diag}([\sigma_1^2(\omega_0) \ \sigma_2^2(\omega_0) \ldots \sigma_D^2(\omega_0)])$ is the source covariance matrix, $\sigma_n^2(\omega_0)$ is the noise variance, $\mathbf{I}$ is an identity matrix, the superscript $(\cdot)^H$ denotes Hermitian operation, and $E\{\cdot\}$ denotes the statistical expectation operator. In practice, (4) is replaced by a sample average.

After forming the covariance matrix, two approaches can be employed to perform high-resolution DOA estimation. The first approach uses covariance matrix augmentation [21]-[23]. Following [22], since the difference coarray is filled between $-(MN + M - 1)d_0$ and $(MN + M - 1)d_0$, a virtual covariance matrix corresponding to an equivalent $(MN + M)$-element filled ULA can be formed by collecting specific elements of the estimated spatial covariance matrix $\mathbf{R}_{xx}(\omega_0)$ into a Toeplitz matrix. The resulting augmented covariance matrix may not always be positive definite and, thus, requires positive definite Toeplitz completion [22]. Subspace-based high-resolution methods can then be applied to the augmented covariance matrix for estimating up to $(MN + M - 1)$ sources. The number of resolvable sources can be increased to $(2M - 1)N$ by considering a partially specified virtual covariance matrix corresponding to an equivalent $(2M - 1)N+1$-element filled ULA [23]. However, this comes at the expense of increased computational complexity due to a complicated and involved matrix completion process.

The second approach vectorizes the covariance matrix $\mathbf{R}_{xx}(\omega_0)$ as [7]

$$\mathbf{z}(\omega_0) = \text{vec}(\mathbf{R}_{xx}(\omega_0)) = \mathbf{A}(\omega_0)[\sigma_1^2(\omega_0) \ \sigma_2^2(\omega_0) \ldots \sigma_D^2(\omega_0)]^T + \sigma_n^2(\omega_0)\mathbf{I},$$

(5)

where $\mathbf{A}(\omega_0) = \mathbf{A}'(\omega_0) \odot \mathbf{A}(\omega_0)$, the symbol ‘$\odot$’ denotes the Khatri-Rao product, the superscript ‘*$\dagger$’ denotes complex conjugation, and $\mathbf{I}$ is the vectorized form of $\mathbf{I}$. The vector $\mathbf{z}(\omega_0)$ acts as the received signal vector of a longer array whose elements positions are given by the difference coarray. However, as the sources are replaced by their powers, the model in (5) is similar to that of a fully coherent source environment. Spatial smoothing can be used to decorrelate the sources [8], [30], provided that only the filled part of the difference coarray between $-(MN + M - 1)d_0$ and $(MN + M - 1)d_0$ is employed. As such, the rank of the smoothed covariance matrix is equal to $(MN + M)$ [8], [11], which allows a maximum of $(MN + M - 1)$ sources to be estimated by applying high-resolution techniques.

III. HIGH RESOLUTION DOA ESTIMATION WITH MULTI-FREQUENCY CO-PRIME ARRAYS

In this section, we describe how dual and multiple frequencies can be utilized to fill the holes in the coarray, thereby permitting the exploitation of the full DOFs that the co-prime configuration has to offer. The sources are assumed to have a bandwidth large enough to cover all frequencies required for filling the holes. Discrete Fourier transform (DFT) or filterbanks are used to decompose the array output vector into multiple non-overlapping narrowband components and extract the received signal at each considered frequency [31], [32]. The observation time is assumed to be sufficiently long to resolve the different frequencies.

Consider the extended co-prime configuration of Fig. 1, where the unit spacing $d_0$ is assumed to be half-wavelength at the reference frequency $\omega_0$. The received signal at $\omega_0$ is the same as in (2), whereas that obtained by operating the physical co-prime array at a different
frequency, \( \omega_q = \alpha_q \omega_0 \), has the form

\[
x(\omega_q) = A(\omega_q) s(\omega_q) + n(\omega_q),
\]

where \( A(\omega_q) \) is the \((2M + N - 1) \times D\) array manifold at \( \omega_q \) with its \((i,j)\)th element given by

\[
[A(\omega_q)]_{ij} = e^{j k_q x_i \sin(\theta_j)}. \tag{7}
\]

In (7), \( k_q = \omega_q / c \) is the wavenumber at \( \omega_q \). Since \( k_q = \alpha_q k_0 \), (7) can be rewritten as

\[
A(\omega_q) = e^{j \omega_0 x_i \sin(\theta_j)}. \tag{8}
\]

Comparing (3) and (8), we observe that the array manifold at \( \omega_q \) is equivalent to the array manifold at \( \omega_0 \) of a scaled version of the physical co-prime array. The position of the \( i \)th element in the equivalent scaled array is given by \( \alpha_q x_i \). This results in the difference coarray at \( \omega_q \) to be a scaled version of the coarray at the reference frequency \( \omega_0 \) [33]. Values of \( \omega_q \) higher than \( \omega_0 \) cause an expansion of the coarray, while the coarray contracts if \( \omega_q \) is lower than \( \omega_0 \). In other words, operation at the additional frequency adds extra points at specific locations in the coarray. A suitable choice of additional operating frequencies will cause some of these extra points to occur at the locations of the holes in the difference coarray at \( \omega_0 \).

A. Virtual Covariance Matrix Formation

Let the total number of operational frequencies, including the reference, be \( Q \). As shown below, a virtual covariance matrix can be constructed using the multi-frequency measurements, which is equivalent to that of a ULA with \((2M - 1)N + 1\) elements operating at the reference frequency [26], [34]. This would allow DOA estimation of \((2M - 1)N\) sources instead of \((MN + M - 1)\) sources using \((2M + N - 1)\) physical sensors of the co-prime array.

A \((2M + N - 1) \times (2M + N - 1)\) support matrix \( C(\omega_q) \) is defined such that its \((i,j)\)th element is given by [26], [34]

\[
[C(\omega_q)]_{ij} = \alpha q x_i - \alpha q x_j. \tag{9}
\]

That is, the \((i,j)\)th element of \( C(\omega_q) \) is the spatial lag or the coarray element position which is the support of the \((i,j)\)th element of the covariance matrix \( R_{xx}(\omega_q) \)

\[
R_{xx}(\omega_q) \text{ = } E \{ x(\omega_q) x(\omega_q) \}^H = A(\omega_q) R_{ss}(\omega_q) A^H(\omega_q) + \sigma_n^2(\omega_q) I, \tag{10}
\]

where \( R_{ss}(\omega_q) = \text{diag}(\{ \sigma_q^2(\omega_q) \sigma_q^2(\omega_q) ... \sigma_q^2(\omega_q) \}) \) is the source covariance matrix at frequency \( \omega_q \). It should be noted that \( C(\omega_q) = \alpha Q C(\omega_0) \), where \( C(\omega_0) \) is the support matrix at the reference frequency \( \omega_0 \). Let \( C_v(\omega_q) \) and \( R_v(\omega_q) \) be the support and the covariance matrices corresponding to the desired ULA with \((2M - 1)N + 1\) sensors operating at \( \omega_0 \). Given that the \( Q \) operational frequencies are sufficient to fill all the holes in the difference coarray of the co-prime array, then

\[
[C_v(\omega_q)]_{ij} = [C(\omega_q)]_{pqr}, \text{ for some } q, p, r, \text{ and all } i \text{ and } j \tag{11}
\]

Let \( h \) be the map that arranges selected elements of the multi-frequency support matrices, \( (C(\omega_q))_{q=0}^{Q-1} \), into the desired virtual support matrix \( C_v(\omega_0) \). Using the same map, the virtual covariance matrix \( R_v(\omega_0) \) corresponding to the equivalent ULA can then be constructed from the covariance matrices \( (R_{xx}(\omega_q))_{q=0}^{Q-1} \) corresponding to the \( Q \) operational frequencies [26].

For illustration, we consider a co-prime array with \( M = 2 \) and \( N = 3 \). The sensor positions of the two uniform linear subarrays are given by \([0, 2d_0, 4d_0]\) and \([3d_0, 6d_0, 9d_0]\), respectively. The support matrix \( C(\omega_q) \) at the reference frequency takes the form

\[
\begin{pmatrix}
0 & -2 & -3 & -4 & -6 & -9 \\
2 & 0 & -1 & -2 & -4 & -7 \\
4 & 2 & 1 & 0 & -2 & -5 \\
6 & 4 & 3 & 2 & 0 & -3 \\
9 & 7 & 6 & 5 & 3 & 0
\end{pmatrix} d_0. \tag{12}
\]

The difference coarray of this configuration is shown in Fig. 3. It has holes at \(-8d_0 \) and \(8d_0 \). In order to fill these holes and form the virtual covariance matrix, an additional frequency \( \omega_1 = 8/9 \omega_0 \) is required. With this choice of the second operational frequency, the support matrix at \( \omega_1 \) is given by

\[
\begin{pmatrix}
0 & 16 & -8 & 32 & -16 & -8 \\
16 & 0 & 8 & 16 & 32 & -56 \\
9 & 9 & 9 & 9 & 9 & 9 \\
8 & 8 & 0 & -8 & -8 & 16 \\
3 & 3 & 9 & 9 & 9 & 9 \\
32 & 16 & 8 & 0 & -16 & 40 \\
9 & 9 & 9 & 9 & 9 & 9 \\
16 & 32 & 8 & 16 & 0 & 8 \\
3 & 3 & 9 & 9 & 9 & 9 \\
8 & 56 & 16 & 40 & 8 & 0
\end{pmatrix} d_0. \tag{13}
\]
The support matrix \( C_v(\omega_0) \) of the desired 10-element ULA, whose elements are positioned at \([0, 1, \ldots, 9]d_o\), has the structure
\[
C_v(\omega_0) = \begin{bmatrix}
0 & -1 & -2 & \ldots & -8 & -9 \\
1 & 0 & -1 & \ldots & -7 & -8 \\
2 & 1 & 0 & \ldots & -6 & -7 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
8 & 7 & 6 & \ldots & 0 & -1 \\
9 & 8 & 7 & \ldots & 1 & 0
\end{bmatrix}.
\]

From (12)-(14), we observe that several possibilities exist for constructing \( C_v(\omega_0) \) using \( C(\omega_0) \) and \( C(\omega_1) \), since several elements of \( C(\omega_0) \) and \( C(\omega_1) \) correspond to the same element of \( C_v(\omega_0) \). Either a single element or an average of all such elements can be used to specify the map for forming the desired virtual support matrix and, subsequently, the virtual covariance matrix \( R_v(\omega_0) \) [26], [34].

It should be noted that since the difference coarray at \( \omega_0 \) has two holes at \( \pm 8d_o \), only those elements of \( R_{xx}(\omega_1) \) that correspond to these two lags are required to form \( R_v(\omega_0) \). This means that instead of operating the entire co-prime array at \( \omega_1 \), only the sensors that produce the \( \pm 8d_o \) lags at \( \omega_1 \) should be operated at the additional frequency. For example, operating the two sensors with positions \([0 9]d_o\) at \( \omega_1 \) produces the following reduced support matrix
\[
C_v(\omega_1) = \begin{bmatrix}
8 & 0 & -9 \\
9 & 0 & 0
\end{bmatrix}d_0 = \begin{bmatrix}
0 & -8 \\
8 & 0
\end{bmatrix}d_0.
\]

The two support matrices \( C(\omega_0) \) and \( C_v(\omega_0) \) can then be combined to form \( C_v(\omega_0) \). This procedure results in reducing hardware complexity. A more detailed discussion in this regard is provided in Section IV-D.

B. Proportional Spectra Requirement

For multi-frequency DOA estimation, the normalized covariance matrices are employed instead of \( \{R_{xx}(\omega_q)\}_{q=0}^{Q-1} \). The \((i,j)\)th element of the normalized covariance matrix \( \tilde{R}_{xx}(\omega_q) \) at frequency \( \omega_q \) can be expressed as [34]
\[
[\tilde{R}_{xx}(\omega_q)]_{ij} = \frac{1}{N_s(\omega_q)} E\left\{ [\mathbf{x}(\omega_q)]_i [\mathbf{x}^*(\omega_q)]_j \right\},
\]
where \( [\mathbf{x}(\omega_q)]_i \) is the \( i \)th element of the data vector at frequency \( \omega_q \), and \( N_s(\omega_q) \) is the number of sensors that are operated at \( \omega_q \). This results in the source and noise powers in the covariance matrix representation of (10) being replaced by the normalized powers [26], which are given by
\[
\tilde{\sigma}_k^2(\omega_q) = \frac{\sigma_k^2(\omega_q)}{\sum_{d=1}^D \sigma_d^2(\omega_q) + \sigma_n^2(\omega_q)}
\]
(17)
\[
\tilde{\sigma}_n^2(\omega_q) = \frac{\sigma_n^2(\omega_q)}{\sum_{d=1}^D \sigma_d^2(\omega_q) + \sigma_n^2(\omega_q)}
\]
(18)
where \( \tilde{\sigma}_k^2(\omega_q) \) is the normalized power of the \( k \)th source at frequency \( \omega_q \) and \( \tilde{\sigma}_n^2(\omega_q) \) is the normalized noise power at the same frequency. The virtual covariance matrix \( R_v(\omega_q) \), constructed by using the normalized covariance matrices \( \{\tilde{R}_{xx}(\omega_q)\}_{q=0}^{Q-1} \) following the procedure outlined in Section III.A, must appear to have been generated by the virtual array as if it were the actual array operating at frequency \( \omega_q \). However, some of the elements of the constructed virtual covariance matrix have contributions from frequencies other than \( \omega_q \). The virtual covariance matrix will be exact provided that the normalized power of each source is independent of frequency,
\[
\tilde{\sigma}_k^2(\omega_q) = \sigma_k^2, \text{ for all } q \in \{0, 1, \ldots, Q - 1\}, \text{ and } k \in \{1, 2, \ldots, D\}
\]
(19)
For a high signal-to-noise ratio (SNR), a sufficient condition for the virtual covariance matrix to be exact is that the sources must have proportional spectra at the employed frequencies [34]. That is,
\[
\frac{\sigma_k^2(\omega_q)}{\sigma_l^2(\omega_q)} = \beta_{k,l}
\]
(20)
where \( \beta_{k,l} \) is a constant for each source pair \((k,l)\) over all frequencies \( \omega_q \). This condition is satisfied, for example, when the \( D \) sources are BPSK or chirp-like signals.

IV. FREQUENCY SELECTION FOR MULTI-FREQUENCY OPERATION USING EXTENDED CO-PRIME ARRAYS

In order to quantify the operational frequency set for filling the holes, we first need to examine the specific structure of the difference coarray corresponding to an extended co-prime configuration. Consider the difference coarray of Fig. 2, which corresponds to the co-prime array of Fig. 1. The total number of filled and missing elements in the coarray equals \(2(2M - 1)N + 1 \), whereas the total number of holes is determined to be \((M - 1)(N - 1)\). As the coarray is symmetric, we only focus on the portion corresponding to the non-negative lags. We observe
that the portion of the coarray extending from 0 to 
\((MN + M - 1)d_o\) is uniform and has no holes. The first 
hole appears at \((MN + M)d_o\), followed by another 
filled part from \((MN + M + 1)d_o\) to \((MN + 2M - 
1)d_o\). The final part of the coarray from \((MN + 2M)d_o\) 
to \((2M - 1)Nd_o\) is non-uniform and contains \(((M - 
1)(N - 1)/2) - 1\) holes.

A. One Additional Frequency (Dual-Frequency 
Operation)

The two holes at \(- (MN + M)d_o\) and \((MN + M)d_o\) 
can be filled using only one additional frequency. The 
choice of the additional frequency is not unique. The 
value of \(\omega_1\) that minimizes the separation between \(\omega_0\) 
and \(\omega_1\) is given by

\[
\omega_1 = \alpha_1 \omega_0 = \frac{MN + M}{MN + M + 1} \omega_0,
\]

(21)

where the numerator and the denominator of the scaling 
factor \(\alpha_1\) correspond to the respective positions of the 
hole to be filled and the adjacent filled element to the 
right of the hole (considering the non-negative lags) 
that is used to fill it. Note that the value of \(\omega_1\) in (21) is 
less than \(\omega_0\). It can be readily shown that using 
neighboring elements other than the right adjacent one 
yields values of \(\omega_1\), which result in a larger separation 
from \(\omega_0\).

Filling the two holes at \(\pm (MN + M)d_o\) causes the 
uniform part of the difference coarray to extend from 
\(-(MN + 2M - 1)d_o\) to \((MN + 2M - 1)d_o\). As a 
result, up to \((MN + 2M - 1)\) sources can be estimated 
after forming the corresponding virtual covariance 
matrix. This implies that, compared to the single 
frequency operation, \(M\) additional sources can be 
estimated using one extra frequency in addition to \(\omega_0\).

B. Multiple Additional Frequencies (Multiple 
Frequency Operations)

The remaining \((M - 1)(N - 1) - 2\) holes in the 
difference coarray can also be filled through the use of 
additional frequencies. The exact number and values of 
the frequencies are tied to the non-uniformity pattern in 
the coarray beyond \(\pm (MN + 2M)d_o\), which varies 
from one co-prime configuration to the other. Assuming 
that each additional frequency is used to fill only two 
holes (one missing positive element and its negative 
counterpart), we require at the most \(\frac{1}{2}((M - 1)(N - 
1) - 2) = (MN - M - N)/2\) additional frequencies to 
yield a filled uniform coarray extending from 
\(-(2M - 
1)Nd_o\) to \((2M - 1)Nd_o\).

C. Maximum Frequency Separation

The maximum frequency separation from the 
reference frequency determines the required operational 
bandwidth of the antennas and receiver front end for the 
proposed multi-frequency approach. It is determined by

the distance of the farthest hole from its nearest filled 
right neighbor and the location of the neighbor. The 
maximum number of consecutive holes in the 
difference coarray is \((M - 1)\) and this pattern of 
\((M - 1)\) consecutive holes repeats \([N/M]\) times at each 
end of the difference coarray, as shown in Fig. 4 for the 
non-negative lags. However, it is the first set of 
\((M - 1)\) consecutive holes (those on extreme left in 
Fig. 4) that requires operational frequencies with the 
maximum separation from \(\omega_0\) in order to be filled. The 
repeated hole patterns at larger lags yield smaller 
frequency separation values. The first missing element 
in the leftmost set of consecutive holes occurs at 
\([(2M - 1)N - (M - 1) - ((N/M) - 1)M]d_o\), while the 
nearest right filled element is positioned at 
\([(2M - 
1)N - ((N/M) - 1)M]d_o\). Therefore, the required 
frequency to fill this hole is given by

\[
\tilde{\omega} = \frac{(2M - 1)N - (M - 1) - ((N/M) - 1)M}{(2M - 1)N - ((N/M) - 1)M} \omega_0
\]

(22)

The maximum frequency separation can, thus, be 
computed as

\[
\Delta \omega_{\text{max}} = |\omega_0 - \tilde{\omega}|
\]

\[
= \left| \frac{1 - M}{(2M - 1)N - ((N/M) - 1)M} \right| \omega_0.
\]

(23)

Table I shows the maximum frequency separation for 
different co-prime array configurations under two 
cases: i) when one additional frequency is used to fill 
the first pair of holes, and ii) when all holes are filled 
using multiple frequencies. For each of the 
aforementioned cases, the additional number of 
estimated sources compared to single frequency 
operation are also specified in Table I. We observe that 
the maximum frequency separation decreases with 
increasing values of \(M\) and \(N\). This is because both the 
holes and the elements that are used to fill them occur 
at larger spatial lags for higher values of \(M\) and \(N\), 
which, in turn, implies a smaller value of the scaling 
factor in (23).

D. Reduced Hardware Complexity

Since only a few observations at each employed 
frequency other than \(\omega_0\) are used for the proposed 
multi-frequency high-resolution DOA estimation 
scheme and the remaining observations are discarded, it 
is not economical to operate the entire physical array at 
each of the additional \(Q - 1\) frequencies. Therefore, 
only the receive elements that generate the desired 
spatial lags for filling the holes need to be operating at 
more than one frequency. As determined in Section
IV.C, the bandwidth requirement for the multi-frequency operation is not that high, especially for larger values of $M$ and $N$. As such, only the multi-frequency receive elements require a DFT or a filterbank to extract the information at the different frequencies, leading to a significant reduction in system hardware complexity.

It becomes of interest to determine the smallest number of sensors that are required to operate at the additional frequency or frequencies. As the holes occur in symmetric pairs, the lags corresponding to each pair can be generated using only two sensors in the physical array. In case of redundancy in the difference coarray, there is more than one antenna pair that can generate the same spatial lag. In order to reduce the number of antennas engaging in multiple frequency processing, one should therefore seek and identify each sensor that participates in filling all the holes or at least many of them. This becomes important when there is flexibility in sensor participation choices implied by the redundancy property of the spatial lags. Clearly, only the redundant spatial lags occurring beyond the first symmetric hole pair at $\pm (MN + 2)d_0$ need to be considered, since these are used to fill the holes in the difference coarray. It can be readily shown that there are a total of $2(M - 2)$ redundant lags beyond $\pm (MN + M)d_0$ at $\pm (MN + kN)d_0$ with weights given by

$$W(\pm (MN + kN)d_0) = M - k,$$

for $k = 1, 2, ..., M - 2$.  

(24)

For illustration, we consider an example where $M = 4$ and $N = 5$. The co-prime array consists of 12 elements positioned at $[0 4 5 8 10 12 15 16 20 25 30 35]d_0$. Fig. 5 shows the difference coarray weighting function corresponding to this array. The first hole pair in the coarray occurs at $\pm (MN + M)d_0 = \pm 24d_0$. Beyond the first holes, $2(M - 2) = 4$ redundant lags exist. The first redundant lag pair occurs at $\pm (MN + N)d_0 = \pm 25d_0$ with weight equal to $(M - 1) = 3$. The second redundant pair occurs at $\pm (MN + 2N)d_0 = \pm 30d_0$ and has a weight of $(M - 2) = 2$. In order to minimize the maximum frequency separation, only the redundant lags that occur immediately to the right of the holes (considering the nonnegative lags) can be used. For the case where $\text{mod}(N, M) = 1$, all the redundant lags in the nonuniform part of the coarray occur immediately after the holes. This can be confirmed by observing the weighting function in Fig. 5. For the case where $\text{mod}(N, M) = M - 1$, none of the redundant lags are immediately to the right of the holes, as illustrated in Fig. 6 for the case where $M = 4$ and $N = 7$. For the remaining cases, only a subset of the redundant lags in the nonuniform part is immediately after the holes.

For the illustration of the role of redundancy in reducing sensor engagement in hole filling, we provide the following two examples. Table II shows the additional frequencies and the corresponding sensor pairs that are required to fill all nine holes in the difference coarray for the case where $M = 4$ and $N = 7$. The corresponding physical array consists of 14 sensors at $[0 4 7 8 12 14 16 20 21 24 28 35 42 49]d_0$. It is clear from Table II that only the 6 sensors located at $[0 4 8 12 16 49]d_0$ are required to operate at more than one frequency in order to fill all the holes in the coarray. It should be noted that since $\text{mod}(N, M) = M - 1$ in this example, the redundant lags in the
The difference coarray cannot be used to further decrease the number of antennas that would operate at more than one frequency. Table III shows the required frequencies and the corresponding sensor pairs for the case where $M = 4$ and $N = 5$. Since $\text{mod}(N,M) = 1$, different sensor pairs can be used to fill the same holes. As shown in Table III, the pairs that include common sensors at different frequencies are chosen in order to minimize the number of sensors that operate at more than one frequency. Table IV shows the percentage of sensors that need to be operated at more than one frequency for different co-prime array configurations. We observe that the number of sensors that need to be operated at multiple frequencies has a lower bound of one-third of the total number of sensors in the array, which is achieved for co-prime configurations with $N = M + 1$. It should be noted that the same choice of $N = M + 1$ also minimizes the total number of sensors in the co-prime arrays, as demonstrated in [15].

V. NUMERICAL RESULTS

In this section, we present DOA estimation results based on the MUSIC algorithm using multi-frequency co-prime arrays. Both proportional and nonproportional source spectra cases are considered and performance comparison with single-frequency operation is provided. We employ the filled part of the coarray and covariance matrix augmentation for DOA estimation using MUSIC under single frequency operation. The root mean squared error (RMSE) in all examples in this section is based on a single realization, unless stated otherwise.

A. Proportional Spectra

We first consider a co-prime array configuration with six physical sensors, corresponding to $M = 2$ and $N = 3$. The first uniform linear subarray consists of three elements positioned at $[0,2d_0,4d_0]$ and the second subarray has four elements with positions $[0,3d_0,6d_0,9d_0]$, with $d_0$ equal to one-half wavelength at $\omega_0$. The difference coarray of this configuration, shown in Fig. 3, has two holes at $\pm 8d_0$, which can be filled using an additional frequency $\omega_1 = (8/9)\omega_0$. We consider 9 sources with proportional spectra, where $\sigma^2(\omega_1) = 3\sigma^2(\omega_0)$ for $d = 0,1,...,8$. The sources are uniformly spaced between $-0.95$ and $0.95$ in the reduced angular coordinate $\sin(\theta)$. A total of 2000 snapshots are used and the SNR is set to 0 dB for both frequencies. The estimated spatial spectrum, where only the reference frequency $\omega_0$ is used, is provided in Fig. 7. The elements in the covariance matrix corresponding to the holes in the difference coarray have been filled with zeros. This is equivalent to the case where the sources have zero powers at the additional frequency. The vertical lines in the figure indicate the true DOAs of the sources. We observe from Fig. 7 that the single frequency approach fails to correctly estimate the DOAs of most of the targets. The RMSE is found to be 2.55°. This is expected since the considered co-prime

Figure 7. MUSIC spectrum using single frequency, $D = 9$ sources with proportional spectra.
array operating at a single frequency can resolve a maximum of 7 sources. Fig. 8 depicts the estimated spatial spectrum using the dual-frequency approach. We can clearly see that the DOAs of all sources have been correctly estimated. In this case, the RMSE of the DOA estimates is equal to $0.67^\circ$.

In the second example, we consider a co-prime configuration with $M = 5$ and $N = 7$. The 7 sensors of the first ULA are positioned at $[0, 5, 10, 15, 20, 25, 30]d_0$, and the second ULA has 10 elements with positions $[0, 7, 14, 21, 28, 35, 42, 49, 56, 63]d_0$. The corresponding coarray extends from $-63d_0$ to $63d_0$ and has a total of 24 holes. The uniform portion of the coarray only extends from $-39d_0$ to $39d_0$. Thus, the single frequency operation can resolve a maximum of 39 sources. One additional frequency $\omega_1 = (40/41)\omega_0$ is first used to fill the holes at $\pm 40d_0$ in the coarray. As a result, the uniform part of the coarray now includes the lags from $-44d_0$ to $44d_0$, thereby increasing the maximum number of resolvable sources from 39 to 44. The sources are assumed to have identical power spectra at the two frequencies. A total of 2000 snapshots are considered and the SNR is set to 0 dB for both frequencies. Fig. 9 shows the estimated spatial spectrum, wherein the DOAs of all 44 sources have been accurately estimated. The RMSE is determined to be $0.31^\circ$ in this case. Next, we employ 12 additional frequencies to fill all 24 holes in the coarray. The additional frequencies and the corresponding holes they fill are listed in Table V. It should be noted that the holes could have also been filled using only six additional frequencies. These frequencies are $\omega_1 = 5\omega_0$, $\omega_2 = 2\omega_0$, $\omega_3 = (47/49)\omega_0$, $\omega_4 = 3\omega_0$, $\omega_5 = (59/63)\omega_0$, and $\omega_6 = (61/63)\omega_0$. However, this choice of frequencies results in a maximum frequency separation of $4\omega_0$, compared to $0.064\omega_0$ for the set of frequencies in Table V. Fig. 10 shows the estimated spatial spectrum corresponding to 63 sources with $\sin(\theta_d)$ uniformly distributed between $-0.97$ and $0.97$. The sources are assumed to have identical power spectra at the 12 frequencies. The SNR and the number of snapshots are taken to be the same as for Fig. 9. Again, the multi-frequency approach has estimated all sources accurately and the RMSE is $0.2^\circ$.

B. Nonproportional Spectra

We evaluate the DOA estimation performance of the multi-frequency co-prime arrays when the condition of proportional source spectra is violated. In the first example, we consider the same array and source configuration as in the first example in Section V.A with $M = 2$ and $N = 3$. However, the 9 sources are now assumed to have nonproportional spectra at $\omega_0$ and $\omega_1 = (8/9)\omega_0$. More specifically, the source...
powers at $\omega_0$ are assumed to be identical and equal to unity, whereas the source powers associated with $\omega_1$ are assumed to independently follow a truncated Gaussian distribution with a mean of 5.5 and a common variance. Two different values of 2.25 and 5.06 are considered for the variance. The variance controls the degree of non-proportionality. A higher variance increases the degree of non-proportionality of the source spectra, whereas a lower variance results in smaller variations in the source powers. Two different values of 2.25 and 5.06 are considered for the variance. The variance controls the degree of non-proportionality. A higher variance increases the degree of non-proportionality of the source spectra, whereas a lower variance results in smaller variations in the source powers. Fig. 11 depicts the RMSE as a function of the variance and the SNR, averaged over 2000 Monte Carlo runs. For comparison, the RMSE corresponding to both single-frequency operation and dual-frequency operation for the case when the sources have proportional spectra are also included. As expected, the single-frequency approach, wherein the elements of the virtual covariance matrix corresponding to the holes in the coarray are filled with zeros, provides the worst performance. Further, the RMSE corresponding to the multi-frequency approach for nonproportional spectra increases with increasing variance. This results in a degradation of the estimation performance. Finally, the multi-frequency approach works best when the spectra are proportional and the SNR is higher.

In the following example, we compare the performance of the multi-frequency approach to single-frequency DOA estimation as a function of the assumed model order. The same array configuration with $M = 2$ and $N = 3$ is used. Two cases are considered in this example. The first case deals with sources with proportional spectra, while the second considers sources with nonproportional spectra. For the nonproportional case, the source powers associated with $\omega_0$ are assumed to be identical and equal to unity, and the source powers associated with $\omega_1$ follow a truncated Gaussian distribution with a mean of 5.5 and a variance 2. In both cases, the actual number of sources is set to 4, and the assumed model order is varied between 4 and 7. 1000 Monte Carlo are considered in this example. Fig. 12 shows the RMSE, averaged over 1000 Monte Carlo runs, as a function of the assumed model order for both cases. In computing the RMSE, only the detected peaks that are closest to the actual source directions were considered. From Fig. 12, we observe that, as expected, the performance of the single-frequency approach is not affected by the nonproportionality of the source spectra. On the other hand, the multi-frequency DOA estimation exhibits superior performance for sources with proportional spectra compared to those with nonproportional spectra. Further, the multi-frequency approach is less sensitive to errors in model order as compared to the single-frequency approach.

The effect of the degree of non-proportionality on DOA estimation performance is next examined for the co-prime configuration of the second example in Section V.A with $M = 5$ and $N = 7$ under both dual and multi-frequency operation. Again, the source powers at $\omega_0$ are assumed to be all equal to unity, whereas the source powers at additional frequencies follow a truncated Gaussian distribution with a mean of 5.5 and a common variance. Fig. 13 provides the RMSE, averaged over 2000 Monte Carlo runs, as a function of SNR and variance under the dual-frequency operation for 44 sources. Similar observations to those in Fig. 11 can be made in this case as well. However, two differences can be noticed by comparing the RMSE plots in Figs. 11 and 13. First, the RMSE takes on lower values for all considered DOA estimation methods and variances for the co-prime configuration with $M = 5$ and $N = 7$. Second, the difference in performance between the single and dual frequency operations for the nonproportional spectra cases is much smaller at higher SNR values in this example. This is due to the
The fact that the ratio of the number of missing elements to the total number of elements in the filled part of the difference coarray is smaller in this example. This results in a smaller percentage of elements in the virtual covariance matrix to come from a different frequency or be filled with zeros for single frequency operation. The RMSE plots for the multi-frequency operation to fill all 24 holes are provided in Fig. 14, which corresponds to 60 sources with \( \sin(\theta_d) \) uniformly distributed between -0.97 and 0.97. The performance difference between multi-frequency operation for sources with non-proportional spectra and those with proportional spectra is even less noticeable in this case, though the RMSE values themselves are slightly higher for high SNR. Also, the single-frequency operation exhibits a higher RMSE since a higher percentage of the virtual covariance matrix elements now have a zero value compared to that for Fig. 13.

The final example in this section examines the estimation performance for varying degree of nonproportionality of the source spectra for different values of \( M \) and \( N \) with the SNR fixed at 0 dB. Both dual-frequency operation for filling only the first hole pair and multi-frequency operation for filling all the holes are considered for each co-prime configuration. For each case, the maximum number of resolvable sources was used. A total of 2000 Monte Carlo runs were considered in this example. The source powers associated with the reference frequency \( \omega_0 \) are identical and equal to unity. For the additional frequencies, the source powers follow a truncated Gaussian distribution with a mean of 5.5 and a common variance. The corresponding RMSE plots as a function of the variance of the source powers are depicted in Fig. 15. In order to have a fair comparison among co-prime arrays of different sizes, each RMSE plot is normalized by the Cramer Rao Bound (CRB) of an equivalent ULA with total number of elements equal to the number of contiguous nonnegative lags in the corresponding difference coarray. By examining Fig. 15, the following observations are in order. First, as expected, a decrease in the variance of the sources spectra results in a reduced estimation error. Second, by comparing the results of dual and multiple frequency operation for fixed \( M \) and \( N \), we observe that, in general, the normalized RMSE error is smaller for the case when more than one additional frequencies are used.

C. Comparison with Sparse Reconstruction

Sparse reconstruction can be used in lieu of MUSIC for DOA estimation using multi-frequency co-prime arrays [35]. Unlike the proposed MUSIC-based approach, all of the lags generated by the multi-frequency operation, in addition to those that fill the holes in the difference coarray, can be utilized for DOA estimation using sparse reconstruction. This is because sparse reconstruction does not require the additional lags to fall on a uniform grid (integer multiples of the
unit spacing). Utilization of all generated lags, in this case, enhances the number of DOFs for DOA estimation, leading to an increased number of resolvable sources. However, the performance of the sparse reconstruction approach is affected by the coherence of the data measurement operator. In addition, it is computationally more expensive than MUSIC.

In order to compare the performance of sparse reconstruction and MUSIC based multi-frequency approaches, we consider the following example. The same array configuration as in the first example in Section V.A is used. Two frequencies, $\omega_0$ and $\omega_1 = (8/9)\omega_0$, are employed; the latter can fill the holes in the corresponding difference coarray so that the multi-frequency MUSIC technique can be applied. Nine sources with directions uniformly spaced between -0.9 and 0.9 in the reduced angular coordinate $\sin(\theta)$ are used, which is the maximum number of sources that can be resolved using the multi-frequency MUSIC approach. Two separate cases are considered in this example. The first case assumes sources with proportional spectra, while the second considers sources with nonproportional spectra. For the latter, the source powers at $\omega_0$ are assumed to be identical and equal to unity, whereas the source powers associated with $\omega_1$ are assumed to independently follow a truncated Gaussian distribution with a mean of 5.5 and a variance of 2. Fig. 16 shows the RMSE, averaged over 1000 Monte Carlo runs, as a function of the SNR for both cases. The SNR is assumed to be identical at both frequencies and is varied from -10 dB to 10 dB with a 2.5 dB increment. It can be readily observed that the multi-frequency MUSIC approach outperforms the sparse reconstruction method for all SNR values when the sources have proportional spectra. In case of sources with nonproportional spectra, the multi-frequency MUSIC method outperforms the sparse reconstruction approach for low values of SNR, whereas both methods achieve similar performance at high SNR values. For both proportional and nonproportional spectra cases, the sparse reconstruction approach exhibits significantly degraded performance at low SNR values. This is expected since the accuracy of the sparse reconstruction methods suffers in high noise cases.

VI. CONCLUSION

A multi-frequency technique has been presented for high-resolution DOA estimation using co-prime arrays. A virtual covariance matrix at the reference frequency is created using elements of the narrowband covariance matrices corresponding to the different employed frequencies. The virtual covariance matrix corresponds to a uniform linear array with a difference coarray of the same extent as that of the co-prime array, except that the coarray of the ULA is filled whereas that of the co-prime array has holes. This permits the co-prime array to handle all of the degrees of freedom offered by the co-prime configuration. Observations and insights were provided with regards to i) the maximum frequency separation required to fill all the holes in the difference coarray, ii) the lower bound on the number of sensors required to operate at more than one frequency, and iii) the performance under non-proportional source spectra case. These insights contribute towards better understanding the offerings and limitations of the proposed multi-frequency approach. Supporting simulation examples were provided for DOA estimation of the proposed approach under both proportional and nonproportional spectra. The results demonstrated that the proposed approach can estimate DOAs with high accuracy for sources with proportional spectra, while for non-proportional spectra, the estimation error varies with the SNR as well as the values of $M$ and $N$. The effect of nonproportionality was shown to be not as significant at high SNR for higher values of $M$ and $N$ as for lower values.
